

# Python Programming – Day 1

**Focus: Foundations that matter**

**Goal: Write your first clean Python programs**

# What is python?

- Python is a **high-level programming language**
- Created by **Guido van Rossum**
- Designed for **readability & simplicity**
- Used by beginners and professionals alike

Guido Van Rossum

# Why Python?

Python is popular because it is:

- Easy to learn
- Powerful
- Widely used

## Use Cases:

- Backend (FastAPI, Django)
- Automation & scripting
- Data analysis & ML
- Cybersecurity & tooling

# Python vs C

## Python

- High-level language
- Easy to read & write
- Uses **indentation** instead of braces
- Dynamically typed
- Garbage collected
- Slower execution (but faster development)

```
1 print("Hello world")
2
3
```

## C

- Low-level language
- Complex syntax
- Uses {} and ;
- Statically typed
- Manual memory management
- Very fast execution

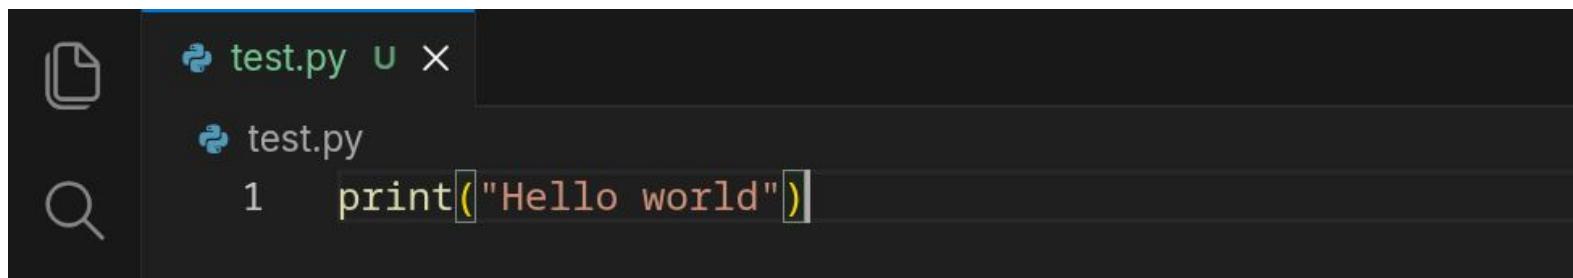

```
1 #include <stdio.h>
2
3 int main(){
4     printf("Hello world");
5     return 0;
6 }
7
```

# Ways to Use Python

## 1. System Python

```
(base) → nvim git:(master) python
Python 3.13.11 | packaged by Anaconda, Inc. | (main, Dec 10 2025, 21:28:48) [GCC 14.3.0] on linux
Type "help", "copyright", "credits" or "license" for more information.
>>> █
```

## 2. IDE

# Ways to Use Python

## 3. Notebook

The screenshot shows a Jupyter Notebook interface running in nvim. The top bar displays the title "nvim". The left sidebar has icons for file operations, search, and notebook settings. The main area contains three code cells:

- Cell 1:** Contains the code `print("Anything")`. The output shows a checkmark and "0.0s". The result is "Anything".
- Cell 2:** Contains the code `print("Anything more")`. The output shows a checkmark and "0.0s". The result is "Anything more".
- Cell 3 (Bottom):** A blank cell with a cursor and a toolbar above it containing icons for cell operations.

The status bar at the bottom right indicates "base (Python 3.13.11)".

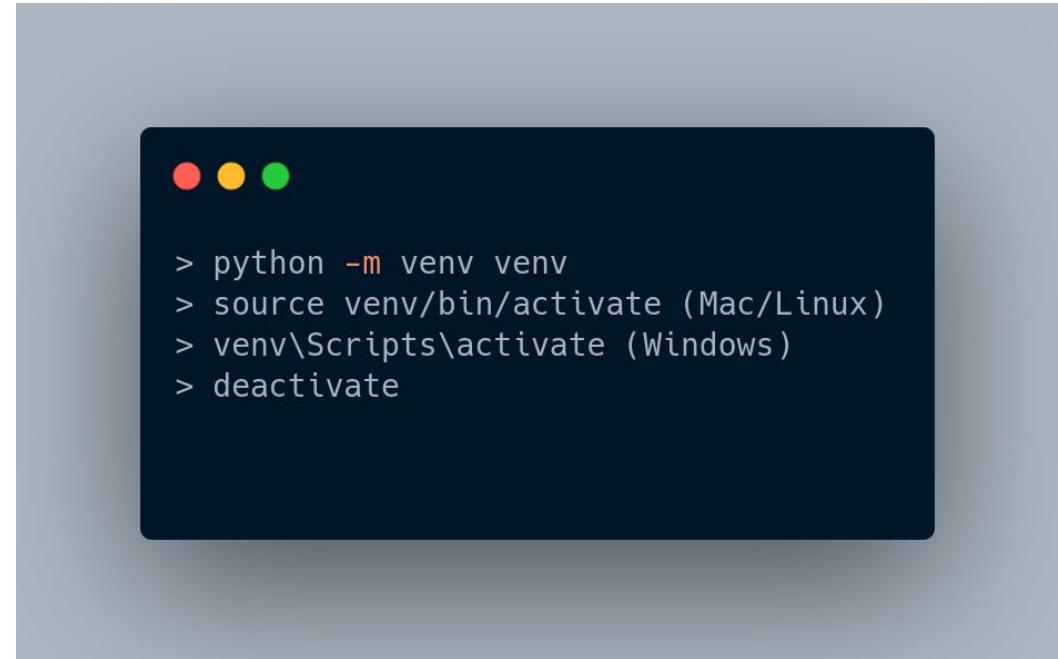

# What is a Virtual Environment?

A **virtual environment** is:

- An isolated Python workspace
- Keeps dependencies separate per project

**Why it matters:**

- Avoids version conflicts
- Clean & professional workflow
- Industry standard

```
> python -m venv venv
> source venv/bin/activate (Mac/Linux)
> venv\Scripts\activate (Windows)
> deactivate
```

# PIP vs UV

## Pip (Most used)

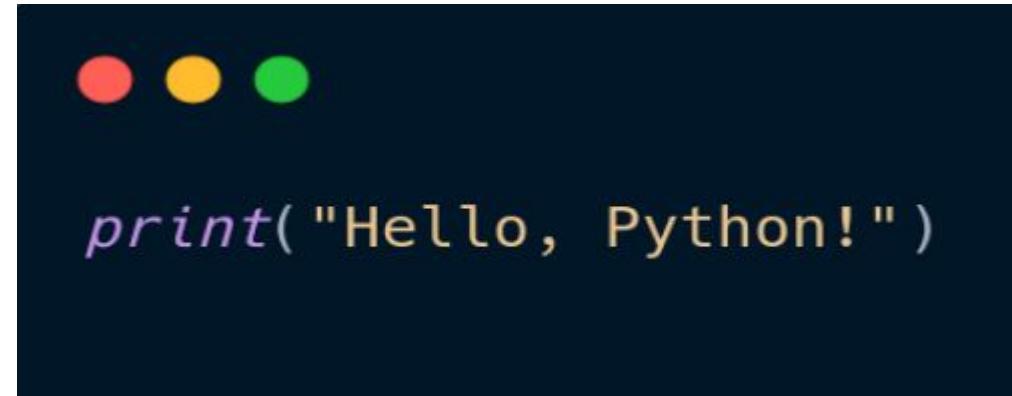

- Traditional Python package manager
- Widely used
- Slower dependency resolution

## Uv (less in used)

- Modern & fast
- Written in Rust
- Better dependency handling

# Your First Python Code

- `print()` outputs text to the screen
- This is your first Python program 🎉

# Variables & Data Types

- Variables store data.
- Common Python data types:
  - `int` → 10, -5
  - `float` → 3.14, 0.5
  - `str` → "hello"
  - `bool` → True / False

```
name = "Ram"  
numb = 7  
char = 'a'  
floating = 1.22
```

# Input & Output

- Output:

```
print("Enter your name")
```

# Input & Output

- Input:

```
a = input('Enter your name')
```

# Type Casting

- Convert one type to another

```
age = int(input("Enter age: "))
height = float("5.9")
```

# Control flow

- Control flow is the way to **control the order in which code executes** in a program.

## Key Components:

- Conditional statements: `if`, `elif`, `else`
- Loops: `for`, `while`
- Loop controls: `break`, `continue`, `pass`

# Control flow (if-elif-else)

```
● ● ●  
age = 20  
  
if age < 13:  
    print("Child")  
elif age < 20:  
    print("Teenager")  
else:  
    print("Adult")
```

# Logical Operators

## What are Logical Operators?

- Logical operators are used to **combine or modify conditions** in Python.

## Common Operators:

- **and** → True if **both** conditions are True
- **or** → True if **at least one** condition is True
- **not** → Reverses a condition

# Logical Operators

```
● ● ●  
age = 20  
citizen = True  
  
if age ≥ 18 and citizen:  
    print("Eligible to vote")
```

# Practice Task

- **Even / Odd Checker**
  - 1. Prompt user to enter a number
  - 2. Read the number and store in variable NUM
  - 
  - 3. IF NUM modulo 2 equals 0 THEN
    - PRINT "Number is Even"
  - ELSE
    - PRINT "Number is Odd"

# HomeWork Question

**Write a Python program that:**

1. Takes three numbers as input from the user
  2. Determines and prints:
    - o The **largest number**
    - o Whether it is **even or odd**
-

# Day 2

By Pujan Neupane

# Loops, Data Structures & Built-ins

By Pujan Neupane

# What Are Loops?

Loops let us **repeat actions** without writing the same code again.

Why loops matter:

- Reduce code repetition
- Handle large data easily
- Automate repetitive tasks

# For Loop

Used to iterate over a sequence (list, string, range, etc.)

Key idea:

- Runs **for each item** in a sequence

```
for i in range(start, stop, step):  
    print(i)
```

# while Loop

Runs **while a condition is true**

Key idea:

- Condition-based repetition

# Loop Control Keywords

Break: Stops the loop immediately

Continue : Skips current iteration, moves to next

Pass : Does Nothing

# Break: Control Keywords

```
for i in range(1, 6):
    if i == 3:
        break
    print(i)
```

# Continue : Control Keywords

```
for i in range(1, 6):
    if i == 3:
        continue
    print(i)
```

# pass : Control Keywords

```
for i in range(1, 4):
    if i == 2:
        pass
    print(i)
```

# Question: What will be printed by this code?

- a. 0 1 2
- b. 0 1
- c. 1 2 3
- d. 0 1 2 3 4

```
for i in range(5):  
    if i == 2:  
        break  
    print(i)
```

## Task

- Write a program to print **all numbers from 1 to 10 except 5**, and stop **if the number is 8**.

# Data Structures in Python

Used to **store and organize data**

Main types:

- List
- Tuple
- Set
- Dictionary

# List

- Ordered collection
- Mutable (can be changed)

# List: Example

```
● ● ●

# List example
fruits = ["apple", "banana", "mango"]
print(fruits)
print(fruits[0])    # apple
fruits[1] = "orange"
print(fruits)
```

# Tuple

- Ordered collection
- Immutable (cannot be changed)

```
# Tuple example
coordinates = (10, 20)

# Access by index
print(coordinates[0]) # 10

# coordinates[0] = 50 (ERR)
```

# Set

- Unordered collection
- No Duplicates
- mutable

```
# Set example
numbers = {1, 2, 3, 3, 4}

print(numbers) # duplicates removed automatically

# Membership testing
print(3 in numbers) # True
print(5 in numbers) # False
```

# Dictionary

- Key–Value Pairs
  - Mutable
- Used for:
- Fast lookups
  - Mapping relationships

```
student = {  
    "name": "Pujan",  
    "age": 20,  
    "course": "Python"  
}  
  
print(student["name"])  
student["age"] = 21  
print(student)
```

# Indexing & Slicing

## Indexing

- Access single element

## Slicing

- Access a range of elements

Works with:

- Lists
- Tuples
- Strings

```
text = "Python"  
nums = [10, 20, 30, 40, 50]  
print(text[0])  
print(nums[2])  
print(text[0:3])  
print(nums[1:4])
```

# Mutability vs Immutability

## Mutable

- Can change after creation
- Example: List, Dictionary

## Immutable

- Cannot change after creation
- Example: Tuple, String

```
# Mutable example (List)
a = [1, 2, 3]
a[0] = 99
print(a)
```

```
# Immutable example (Tuple)
b = (1, 2, 3)
# b[0] = 99      error
print(b)
```

# Task: CODE

**Question:** Create a **list of fruits**, a **tuple of colors**, and a **set of numbers**.

Then:

- Add a new fruit to the list
- Try changing a tuple element (observe error)
- Add a new number to the set

# Built-in Functions

`len()` – count items (already done)

`type()` – check data type (already done)

`range()` – generate numbers (already done)

`sorted()` – sort data

`enumerate()` – index + value

`sum()` – total

`min()` – smallest value

`max()` – largest value

## sorted( ) – sort data

```
numbers = [5, 2, 9, 1, 3]
```

```
sorted_numbers = sorted(numbers)
```

```
print(sorted_numbers)
```

## enumerate() – Index + Value

```
fruits = ["apple", "banana", "mango"]

for index, value in enumerate(fruits):
    print(index, value)
```

## sum( ) – Total

```
numbers = [10, 20, 30]
```

```
total = sum(numbers)
```

```
print(total)
```

## min() – Smallest Value from the list

```
numbers = [10, 5, 30, 2]
```

```
print(min(numbers))
```

## max() – Largest Value from the list

```
numbers = [10, 5, 30, 2]
```

```
print(max(numbers))
```

# Task: CODE

**Question:** Given a list of marks [ 40, 55, 70, 85 ], write a program to print:

- Total marks
- Highest mark
- Lowest mark
- Marks sorted in ascending order

# Day 3

By Pujan Neupane

# Function && Clean Code

By Pujan Neupane

# What is a Functions?

A **function** is a reusable block of code that performs a specific task.

Why functions matter:

- Reduce code repetition
- Improve readability
- Easier debugging and maintenance

# Defining a Function

```
def function_name():
    # code block
    pass
```

# Example of a Function

```
def greet():
    print("Hello, World!")
```

```
greet()
```

# Parameters & Return Values

- Parameters allow data to be passed into a function.

Key points:

- `return` sends data back to the caller
- A function can return multiple values

```
def add(a, b):
    return a + b

result = add(4, 6)
print(result)
```

# Default Arguments

- Default arguments provide a fallback value.
- Why use defaults?
  - Prevent errors
  - Make functions flexible

```
def greet(name="User"):
    print("Hello", name)

greet()
greet("Pujan")
```

# Keyword Arguments

- Arguments passed using parameter names.

```
● ● ●  
def user_info(name, age):  
    print(name, age)  
  
user_info(age=20, name="Pujan")
```

## \*args (Variable Arguments)

- Used to pass multiple positional arguments.

```
● ● ●

def total(*args):
    return sum(args)

print(total(1, 2, 3, 4))
```

# \*\*kwargs (Keyword Arguments)

- Used to pass multiple keyword arguments.

```
def profile(**kwargs):  
    for key, value in kwargs.items():  
        print(key, value)  
  
profile(name="Pujan", role="Student")
```

# Question: Use args and kwargs

- **Magic Number Machine**

Write a function that:

- Accepts **any number of integers** using `*args`
- Prints:
  - the **total count** of numbers
  - the **sum**
  - the **largest number**

```
magic_numbers(5, 10, 3, 25, 7)
```

# Question: Use kwargs

## - Character Profile Builder

Write a function that:

- Accepts **character details** using **\*\*kwargs**
- Prints a **game-style profile**

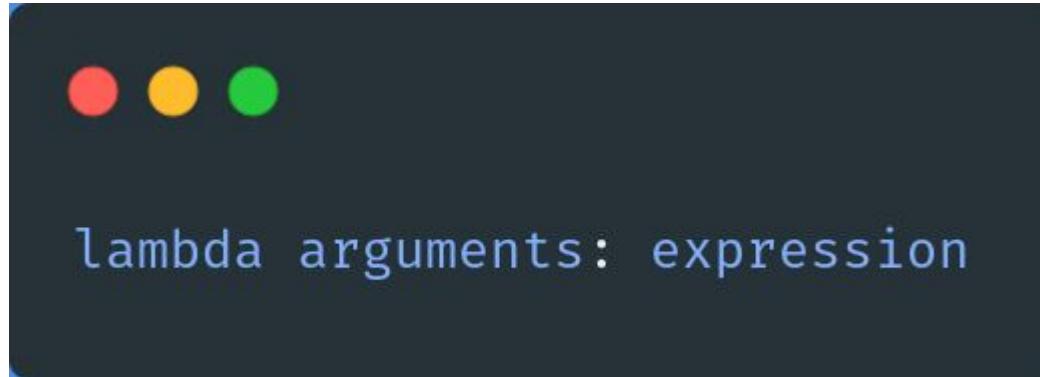

```
character(name="Pujan", level=5, power="Python", hp=100)
```

Character Profile

Name :	Pujan
Level :	5
Power :	Python
HP :	100

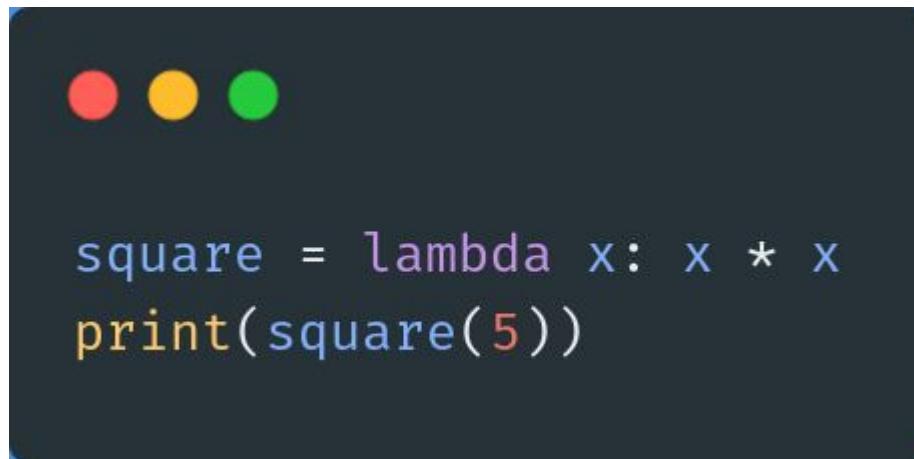

# Lambda Functions

- Anonymous one-line functions.

# Lambda Functions example:

- Anonymous one-line functions.

A screenshot of a terminal window with a dark background. At the top, there are three colored dots: red, yellow, and green. Below them, the following Python code is displayed:

```
square = lambda x: x * x
print(square(5))
```

# Scope (Local vs Global)

Local variables:

- Defined inside a function
- Accessible only within that function

Global variables:

- Defined outside functions
- Accessible everywhere

```
x = 10
def demo():
    x = 5
    print(x)
demo()
print(x)
```

# Docstrings

- Docstrings describe what a function does.

```
def add(a, b):  
    """Returns the sum of two numbers"""  
    return a + b
```

# Function Naming

Good naming rules:

- Use lowercase
- Use underscores
- Be descriptive

Examples:

- `calculate_total()`
- `get_user_data()`

Avoid:

- `func1()`
- `x()`

# Reusability & Best Practices

Best practices:

- Keep functions small
- Do one task per function
- Avoid hardcoding values

Reusable functions:

- Save time
- Improve scalability

# OOP

- By Pujan Neupane

# What is OOP?

**Object-Oriented Programming (OOP)** is a way of structuring programs using **classes** and **objects**.

## Why OOP?

- Organizes code better
- Improves reusability
- Models real-world entities

# Class & Object

## Class

A blueprint for creating objects.

## Object

An instance of a class.

```
class User:  
    pass  
u1 = User()
```

## `__init__` Method

- Special method (constructor)
- Runs automatically when an object is created

```
class User:  
    def __init__(self, name):  
        self.name = name
```

# Instance vs Class Variables

- **Instance variable** → unique per object
- **Class variable** → shared among all objects

```
● ● ●

class User:
    role = "member" # class

def __init__(self, name):
    self.name = name
    # instance variable
```

## Theory Question:

- Why do we use the `__init__` method?
- What is the difference between a class and an object?

## Coding Question:

- Create a **Car** class with attributes: **brand**, **model**, **year**.
  - Create 2 objects and print their details.
  - Add a method **age()** to the **Car** class to calculate the age of the car (current year - year of the car).

soln:

```
# Car Class Example
class Car:
    def __init__(self, brand, model, year):
        self.brand = brand
        self.model = model
        self.year = year

    def display(self):
        print(f"{self.brand} {self.model} ({self.year})")

    def age(self, current_year):
        return current_year - self.year

# Objects
car1 = Car("Toyota", "Corolla", 2018)
car2 = Car("Honda", "Civic", 2020)

car1.display()
car2.display()
current_year = 2025
print(f"Car1 Age: {car1.age(current_year)} years")
print(f"Car2 Age: {car2.age(current_year)} years")
```

# Magic Methods

- Magic methods start and end with double underscores.
- Examples:
  - `__init__`
  - `__str__`
  - `__repr__`

## `__str__` Method

- Defines **user-friendly** string output

```
● ● ●

class User:
    def __init__(self, name):
        self.name = name

    def __str__(self):
        return f"User name is {self.name}"
```

## `__repr__` Method

- Used for **developer/debugging** representation

```
● ● ●  
class User:  
    def __repr__(self):  
        return f"User(name={self.name})"
```

## Question: code

- Create a `Book` class with attributes: `title`, `author`.
  - Use `__str__` to print: "Book: <title> by <author>"
  - Use `__repr__` to print developer-friendly format:  
`"Book(title='<title>', author='<author>')"`

What happens if you print the object without defining `__str__`?

soln:

```
# Book Class Example
class Book:
    def __init__(self, title, author):
        self.title = title
        self.author = author

    def __str__(self):
        return f"Book: {self.title} by {self.author}"

    def __repr__(self):
        return f"Book(title='{self.title}', author='{self.author}')"

b1 = Book("1984", "George Orwell")

print(b1)          # calls __str__
print(repr(b1)) # calls __repr__
```

# Inheritance

- Inheritance allows a class to acquire properties of another class.

```
● ● ●

class Animal:
    def speak(self):
        print("Animal speaks")

class Dog(Animal):
    pass
```

# Polymorphism

- Same method name, different behavior.

```
class Dog:  
    def speak(self):  
        print("Bark")  
  
class Cat:  
    def speak(self):  
        print("Meow")
```

## Method Overriding

- Child class modifies parent method.

```
class Dog(Animal):  
    def speak(self):  
        print("Dog barks")
```

# Operator Overloading

- Redefining operators using magic methods.

Examples:

- `+` → `__add__`
- `==` → `__eq__`

# Operator Overloading : Example

```
● ● ●

class Number:
    def __init__(self, value):
        self.value = value
    def __add__(self, other):
        return Number(self.value + other.value)

    def __str__(self):
        return str(self.value)
n1 = Number(10)
n2 = Number(20)
print(n1 + n2)
```

## Question:

### Create a **Distance** class:

- Attributes: **feet, inches**
- Overload the **+** operator to **add two distances**.
- 12 inches = 1 foot (handle overflow properly)
- Add a **\_\_str\_\_** method to display in "**X ft Y in**" format

```
d1 = Distance(5, 8)
d2 = Distance(3, 9)
print(d1 + d2)
```

# Files, Errors & Standard Library

- By Pujan Neupane

## File Handling – Basics

Reading a Text File:

```
with open("data.txt", "r") as f:  
    content = f.read()  
    print(content)
```

## File Handling – Basics

Write a Text File:

```
with open("data.txt", "w") as f:  
    f.write("Hello, Python!\n")
```

# File Handling – Basics

## File Modes:

r → Read

w → Write (overwrite)

a → Append

rb / wb → Binary modes

```
with open("log.txt", "a") as f:  
    f.write("New log entry\n")
```

# File Handling – Basics

## Write in JSON Files

```
import json

data = {
    "name": "Pujan",
    "role": "Cybersecurity"
}

with open("user.json", "w") as f:
    json.dump(data, f, indent=4)
```

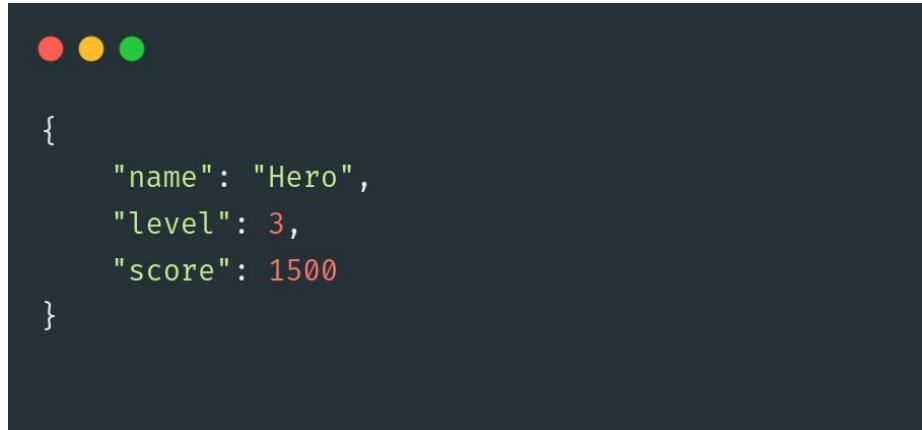

## File Handling – Basics

### Reading JSON Files

```
with open("user.json", "r") as f:  
    data = json.load(f)  
    print(data["name"])
```

## Question

- JSON is used to save the player's game progress.
- Player data is stored as key–value pairs.
- The data is written to a file so it can be loaded later.

A screenshot of a terminal window with a dark background. In the top-left corner, there are three small colored circles: red, yellow, and green. The main area of the terminal contains the following JSON code:

```
{  
    "name": "Hero",  
    "level": 3,  
    "score": 1500  
}
```

# Question

Solution:

```
● ● ●

import json

# create player data
player = {
    "name": "Hero",
    "level": 1,
    "score": 0
}

# write to json file
with open("savegame.json", "w") as file:
    json.dump(player, file, indent=4)

print("Game saved successfully!")
```

# Exception Handling – Basics

```
● ● ●  
try:  
    x = int(input("Enter a number: "))  
    print(10 / x)  
except ValueError:  
    print("Invalid input")  
except ZeroDivisionError:  
    print("Cannot divide by zero")
```

# Exception Handling – Basics

```
● ● ●  
try:  
    x = int(input("Enter a number: "))  
    print(10 / x)  
except ValueError:  
    print("Invalid input")  
except ZeroDivisionError:  
    print("Cannot divide by zero")
```

# Exception Handling – Basics

Try

Except

Else

finally

```
try:
    f = open("data.txt")
except FileNotFoundError:
    print("File not found")
else:
    print(f.read())
finally:
    print("Execution finished")
```

## Exception Handling – Task

Write a Python program that:

- Takes a number as input
- Converts it to an integer
- Handles **invalid input** using **ValueError**

# Exception Handling – Task

```
try:  
    number = int(input("Enter a number"))  
except ValueError:  
    print("invalid input")  
else:  
    print(number)
```

## MODULES :

datetime Module :

### Why **datetime**?

- Work with current date & time
- Create timestamps for logs
- Format date/time for humans or systems

## Datetime

```
from datetime import datetime
now = datetime.now()
print(now)
print(now.strftime("%Y-%m-%d %H:%M:%S"))
```

## `os` Module (Operating System Interaction)

### Why `os`?

- Interact with file system
- Manage folders & paths
- Environment-level operations

## os Module (Operating System Interaction)

```
# Get Current Working Directory
import os
print(os.getcwd())
#Create a Directory
os.mkdir("logs")
#Check If File or Folder Exists
print(os.path.exists("logs"))
```

# `sys` Module (System-Level Access)

## Why `sys`?

- Access Python runtime info
- Read command-line arguments
- Control program execution

## sys Module (System-Level Access)

```
import sys  
print(sys.argv)
```

## Practice – Log Generator

```
● ● ●

from datetime import datetime
import uuid

log_id = uuid.uuid4()
time = datetime.now()

with open("app.log", "a") as f:
    f.write(f"[{time}] {log_id} - User logged in")
```
